RANGE NUTRITION ON CALIFORNIA ANNUAL GRASSLANDS

J. R. Dunbar and M. R. George¹

FORAGE PRODUCTION AND UTILIZATION

Matching the nutrient demands of livestock and the nutrients supplied by range forage comprises a real balancing act for a considerable portion of each year. Operators should know the basic needs of their stock at all times during the production cycle. However, the changes in nutritional status of the animal's diet from day to day as the season progresses is not so well known. Range forage nutritional values may vary greatly from one location to another. The examples of nutrient composition presented in this report are useful indicators of general trends and may aid in supplementation decisions.

Forage Quality

Measures of forage quality such as protein, energy, vitamins and minerals follow a declining trend as the growing season progresses (Figure 1). Conversely, measures of low quality such as fiber and lignin increase as forage plants mature. Seasonal forage quality and phenological stage of several important annual range forage species are reported in Tables 1-3. Note that crude protein levels of the grasses are often in excess of 20 percent at the start of growth in fail but decline at different rates to 5 percent or less by the end of the season. Seasonal trends of forbs (herbaceous plants other than grasses) are similar, although protein levels of legumes are higher than grasses in mid to late season. However, the leaves of forbs, where nutrients are often concentrated, may shatter when the plant drys. This then renders those nutrients unavailable.

Cyclical changes in phosphorus, copper, calcium, potassium and sodium in range forage at the U.C. Sierra Foothill Range Field Station are shown in Figures 2-6. Generally these nutrients are greatest in the spring and lowest during the dry season.

Weather Influences

The new fall growing season begins when rains start germination of stored seed (George et al. 1985). Cattle grazing this forage may lose weight, thus the term inadequate green forage (Bentley and Talbot 1951) (Figure 7). The onset and length of this period of inadequate green forage is dependent on prevailing weather conditions. If the fall and winter period is dry or cold then green feed production will be poor and range supplementation may be necessary to maintain cattle performance. If warm weather coincides with adequate precipitation, then forage production will be greater and animal performance will improve. Dry residual forage from the previous growing season is commonly available for grazing and provides energy but is low in protein and other vital nutrients. Leaching due to precipitation further decreases the nutritional quality of dry residue. The inadequate green forage may contain adequate energy, protein, phosphorus and vitamin A on a dry matter basis, but because of high forage water content livestock are unable to consume adequate forage to meet their need for these nutrients.

Rapid spring growth commences with warming conditions in late winter or early spring (Figure 8). This is also the period when animal performance improves. This period is commonly called the rapid spring growth or adequate green forage season. This forage is usually nutritionally adequate for growth, maintenance and gestation. Rapid spring growth continues for a short time until soil moisture is exhausted. Peak standing crop occurs at the point where soil moisture limits growth or when plants are mature. This period is followed by the summer dry season when the forage is a fair energy source but is low in protein, phosphorus, carotene and other important nutrients (Figure 9). Livestock performance during this period may be poor without supplementation. During this summer period it is common practice to provide supplements, transport the livestock to high elevation green feed or to use irrigated pasture.

Diet Selection and Intake

For a plant to have value it must be selected and grazed by stock, and it must contribute substantially to the digestible nutrients of the diet. Figure 10 shows the seasonal variation in species composition in the diet of beef cows during a below-average rainfall year at the San Joaquin Experimental Range. During the summer and fall cow diets were dominated by dry forage. With the onset of fall rains the proportion of dry residue (leached dry forage) in the diet declined and green forage increased. The top of the chart shows that the winter was drier than normal but storms were rather uniformly distributed. The dry forages at the start of the 12 month period were produced in the extremely wet preceeding year. It is suggested that the low rainfall produced a forage crop low in legumes and rushes.

Selectivity by grazing animals is important in determining value of the plant species on a particular range. The range species composition has a great bearing on the forage value obtained from it.

Figure 7. Variations in length of time that green forage was inadequate on foothill range at the San Joaquin Experimental Range.

Figure 8. Variations in length of time that green forage was adequate on foothill range at the San Joaquin Experimental Range.

Figure 9. Variations in the length of time that cattle grazed almost entirely on dry forage on foothill range at the San Joaquin Experimental Range.

Organic matter intake (Figure 11) and digestibility (Figure 12), was greatest in April and early May in a Sierra Foothill Range Field Station study (Morris 1985, Morris and Delmas, 1980). Protein consumed by fistulated steers (Figure 13) was greatest in March (Morris and Delmas, 1980). Each of these indicators of forage quality measured at the U.C. Sierra Foothill Range Field Station near Marysville, California reached their peak during the period of rapid spring growth described above. Likewise each of these indicators reached its minimum during the summer or fall dry season.

Unpalatable plants do not necessarily have poor nutritive value, but they are rendered of low value because they generally are not selected. It is possible to minimize the effects of selective grazing by forcing uniform use during particular seasons, but the animals may not perform quite as well. Where grazing is not forced stock will select the most palatable plants first.

Cattle tend to select diets that are higher in protein and lower in fiber than that contained on the average in the available forage. Protein in the diet can become limiting before energy, especially for young stock and lactating cows. This is one of the main reasons why performance of these classes of cattle declines sharply when the forage matures (Raguse et al. 1985). As plants mature selectivity may increase.

For optimum production the animal must be able to consume enough quality forage to meet its nutrient requirements. Forage intake is especially important early in the plant's growth period because the high moisture in young forage can limit total dry matter intake.

As the green forage season progresses the quality of forage species diverges due to differing rates of maturity. As more species mature forage quality declines rapidly and becomes limiting. As this occurs the manager has the option of moving stock to areas of less mature forage, supplementing, or modifying the demand by weaning the calves or taking off yearlings. Often, forage value differences may occur within a fairly short geographical distance. For example, species mature later on cool slopes and at higher elevations or in moister swales. Grazing these areas at later dates is commonly done to extend the season of acceptable forage value.

Digestive Physiology

The ruminant can survive, grow, and reproduce on forage alone because of the bacteria, protozoa, fungi and other microbes in the reticulo-rumen section of the digestive tract. During microbial fermentation volatile fatty acids, ammonia, methane and carbon dioxide are released and energy is liberated for growth of the microbial populations. Then the microbes are swept out of the rumen to the abomasum and small intestine with fluid and feed particles and may furnish nutrients needed by the ruminant animal. Ruminal bacteria can use various sources of nitrogen, primarily ammonia, amino acids and peptides, along with energy and minerals for growth. Limited amounts of non-protein nitrogen sources such as urea, are commonly fed to ruminant animals in range supplements.

Figure 12. Seasonal variation in organic matter digestibility (%) of range forage samples collected by esophageal fistulated steers.

Figure 13. Seasonal variation in nitrogen (%) and crude protein (%) in range forage samples collected by esophageal fistulated steers.

STAGES OF PRODUCTION

The beef cow's stage of production should be one of the major criteria in planning a cow herd nutrition program. There are various ways of looking at the stage of production, but one of the best ways is to consider the 365-day beef-cow year, starting with calving and ending with the production of the next calf, Figure 14.

Time of Calving

Fall calving is a common practice on California's annual rangelands because of mild winters with available green forage. Spring calving is commonly practiced in regions of more severe winter weather.

The major factors related to the feasibility of fall or spring calving are:

- 1. Weather conditions
- 2. Availability and nutritive value of the forage and the use of supplemental feed
- 3. Labor
- 4. Capital inputs
- 5. Calf crop percentage
- 6. Relative weights of calves produced
 - in the different calving seasons
- 7. Foothill abortion which affects cows 3-6 months pregnant during April 15 June 1.

Figures 15 and 16 illustrate fall and spring calving and the variations in the periods of adequate green forage, deficient dry forage and the possible need for supplementation.

Rebreeding and Cow Condition

Cows must rebreed within 80-85 days after calving if a 365 day calving interval is to be maintained. Cow condition at the time of calving is an important factor determining how quickly a cow returns to estrus following calving. By monitoring the body condition of their cows, cattle producers can adjust feeding levels to insure an adequate rebreeding rate.

The importance of condition at calving time and cow rebreeding performance is illustrated in Table 4. Experience and research have shown that cows need to be in condition class six or seven to consistantly rebreed at 90% or better. Lusby (1983) discusses the condition scoring system. The system classifies cows from 1 (very thin) to 9 (very fat). Condition classes 6 and 7 indicate animals with a good smooth appearance or in very good flesh.

Period 1 (45 days)

This is the period after calving when the cow is lactating at her highest level to meet the demand of rapid calf growth. In addition, she must undergo uterine involution in preparation for the next pregnancy. She must also start recycling in order to produce a calf in

12 months. Flushing at this time will help to bring the cow in heat and prepare the uterus for the new embryo. It will also help insure an adequate milk supply for optimum calf growth.

Period 2 (45 days)

In this period the cow should rebreed. In a fall calving situation with cows out on range or pasture and lactating during adverse winter months, risk of inadequate nutrition is great. Energy requirements during Periods 1 and 2 are fairly high, and adequate protein, minerals, and vitamins are especially important because of the high level of milk production. During Periods 1 and 2 cows require 112 percent more protein, 36 percent more energy, and 124 percent more calcium and phosphorus than during gestation. If the cow is poorly fed during Periods 1 and 2, it can affect: milk production, calf growth, estrus, conception rate, pregnancy, and loss of weight. To the beef cow and cattleman, Periods 1 and 2 are the most important nutritional periods.

Period 3 (90 days)

During this 90-day period the cow should be in early pregnancy while still lactating and maintaining a calf. If the cow is poorly fed during the period, it will primarily affect her milk production level and her suckling calf's growth rate.

Period 4 (90 days)

This period includes the time immediately before and after weaning the calf. During this time the beef cow's main function is to maintain her developing fetus. The beef cow's nutritional needs at this time are the lowest level in the cycle. During this period, some low quality forages such as straw or crop residues can be used to good advantage to lower feed cost provided they are properly supplemented.

Period 5 (90 days)

This is the third most important period of the cow's year because during it 70 to 80 percent of the fetal growth occurs. In addition, the cow should be gaining weight in preparation for the coming lactation period. This last 90 days before calving is a period when a cattleman can do an awful lot to insure proper calf birth weight, liveability, and growth rate (Table 5).

NUTRIENT REQUIREMENTS

One of the main factors in planning a cow herd supplementation program is the cow's nutritional requirements, and a critical factor that influences these requirements is the stage of production. Listed in Table 6 are the estimated requirements for a 1000 pound beef cow in each of the five periods. The nutrients which should be considered as potentially deficient in annual grasslands of California are energy, protein, phosphorus, magnesium, sodium chloride, certain trace minerals and vitamin A.

Energy

Energy, often measured as total digestible nutrients (TDN), Net Energy for maintenance (NEm), Net Energy for gain (NEg), Digestible Energy (DE), or Metabolizable Energy (ME), is the most important nutritional factor to consider for beef cows for several reasons. It is the nutritional factor most commonly lacking due to the shortage of forage. Were it not for energy, the nutrient requirements of the beef cow could be met by 2-4 pounds of total feed per day. Insufficient

energy intake may occur when cattle are forced to graze deficient dry forage in the fall (inadequate green season).

| ¥ | May be complicated by protein, mineral | ¥ |
| ¥ | and/or vitamin deficiency | ¥ |
| × | | × |

Protein

Protein is the nutrient most likely to be lacking in summer and fall diets when dry forage is plentiful but green forage is not adequate. Supplemental protein for wintering cows is usually the largest cash expense in the yearly costs of maintaining a cow. Supplements such as cottonseed and safflower oil meal are primary sources. Urea is a non-protein compound which ruminants may convert to protein with varying degrees of efficiency through the action of microorganisms in the rumen. The use of liquid supplements and blocks has increased drastically over the past few years and will continue to increase as research provides information on efficient formulations including urea. Presently, urea has a low to moderate value for cattle on dry range when it replaces protein in a natural protein supplement. Proper management procedures are important when urea is fed to prevent ammonia toxicity and to enhance urea utilization.

Magnesium

Under California conditions grass tetany or hypomagnesemic tetany often occurs. It is a major problem especially in lactating cows grazing lush rapidly growing patures highly fertilized with nitrogen during cool foggy seasons. Grass tetany can be prevented by providing 8 grams of magnesium per head per day.

Trace Minerals

Deficiencies of trace minerals such as copper, iodine and selenium exist in many areas of California. It may be desirable to provide a trace mineralized salt mix as a precautionary measure if there is any reason to suspect a deficiency. Selenium deficiencies are concentrated in northern (especially northeastern) California. Selenium can be administered as an injection or as a pellet placed in the reticulum. Selenium provided in supplement blocks has generally not proved effective.

| ¥ | | × |

| ¥ | Diarrhea | × |
| * | | * |

Salt

Vitamin A

Vitamin A deficiencies in beef cow herds occur in California. A cow stores up several months supply in her liver during the adequate

green feed period, but this supply can be rapidly depleted in a lactating cow. Vitamin A deficiencies may also occur in fall calves during dry years or in young cows.

| × | | × |

| <u>*</u> | · | <u>.</u> * |

Supplemental vitamin A should be provided by:

- I. Adding it to a protein supplement
- 2. Injecting it intramuscularly (one million
 - international units will last 3 months);
- 3. Adding it to a mineral mix.

Potassium

Generally, forages contain more potassium than required by beef cows. However, potassium concentration decreases with advancing maturity of forage and can be reduced further by leaching. Potassium deficiency results in decreased feed intake, decreased milk yield, reduced weight gain and muscular weakness.

RANGE SUPPLEMENTATION

Supplementation means making up the difference in quality between what range forage provides and what cattle need. Supplementation does not mean substituting purchased feed for range forage. A supplement should be designed and fed to enhance the utilization of the total diet. Successful supplementation requires the producer to know what nutrients are deficient, the degree of deficiency and the economics of alternative supplemental feeds.

| × | | × |

It has been demonstrated that small amounts of supplement, usually protein, can enhance utilization and animal performance on low quality forage. Table 7 shows the effect of protein supplements on heifer weights while eating grass hay or grazing dry range. In the first experiment, weight gain increased as the level of protein increased, as would be expected. But, in the second experiment, 1 lb. of 40% protein supplement gave performance equal to 2 lbs. of 20% protein feed. This effect usually holds true whenever there are adequate quantities of low quality forage.

Frequency of Supplementation

Contrary to some opinions, cattle do not require daily supplementation. Table 8 summarizes the effect of feeding cattle daily, three times per week, and bi-weekly. This data shows that it makes no difference whether the supplement is fed at a given rate each day, tri-weekly, or bi-weekly. Even if the cows are not fed daily, they should be observed as often as necessary, especially during the pre and post-calving season. Similar results were found in a Nebraska study, where heifer calves were fed a daily allowance of Alfalfa Hay (4 lbs), at daily, weekly or bi-weekly intervals (Table 9).

Cow Life Span

Due to the high cost and time interval rquired to develop a replacement helfer and place her into production, a maximum life span of the beef female is of great economic importance. Limited research suggests that once a beef female meets her needs for optimum growth and reproduction, to feed her in excess of this need may be detrimental. A shortage of feed could also prove to be a liability (Table 10).

Forms of Supplements

Dry roughages, alfalfa, grass or grain hay can be used but should be analyzed to determine nutritive value. Qualilty hays properly supplemented often result in a satisfactory supplemental feeding program.

Dry supplements may be furnished as meals, blocks or cubes. Blocks and cubes have the advantage that they may be fed on the ground whereas meals require the use of a feeder. Intake of meals can be successfully controlled by the use of salt. Hardness has also been used successfully to limit supplement intake.

Molasses or other feed by-products such as corn steep liquor or ammoniated whey are the principle ingredients of liquid supplements. Liquid supplements are easily handled and dispensed by liquid feed companies.
