The goldspotted oak borer (GSOB) has killed tens of thousands of mature oak trees throughout San Diego County and in isolated areas of Orange, Los Angeles, Riverside, and San Bernardino Counties. Experts believe this non-native oak pest was introduced into San Diego County from Arizona – and from San Diego County into other locations by the transport of infested firewood. It poses a threat to many more areas of California. Learn to identify GSOB and keep it out of your communities.

Don’t move firewood!

Moving firewood has the potential to introduce this new pest to more California locations.

Please, do not move firewood!

Black or red staining on the main stem or larger branches can signify injury from the goldspotted oak borer.

High densities of larval galleries can patch kill areas of inner bark and lead to tree death. Patches of dense galleries are often indicated by dark, wet staining on the bark exterior.

Feeding galleries of the goldspotted oak borer larvae are often black in color with no specific pattern. Larvae feed under the bark primarily on the wood surface.

Woodpeckers chip away outer bark to forage on goldspotted oak borer larvae. Woodpecker foraging in coast live oak exposes the dark larval galleries and inner bark.

When new adult beetles emerge, they create D-shaped exit holes about 3/16 of an inch (4 mm) in diameter. These exit holes indicate that tree damage is extensive.

Twig die-back and crown thinning can be symptoms of goldspotted oak borer injury.

Coast live oak is an evergreen species with cupped leaves. Its acorns are slender and sharply pointed.

California black oak is a deciduous species that is found at higher elevations, 5,000-7,000 feet in southern California.

Canyon live oak is an evergreen species. The underside of older leaves appear gray; newer leaves have fine red hairs.
